Problem Set 6 Solutions

Question 1. This problem will use the dataset described in the midterm. You are interested in the effects that eliminating school fees had on childrens' school enrollment in sub-Saharan Africa. You have annual country-level data on school enrollment rates from 1981 to 2015 for 15 countries and the year in which each country eliminated fees. (Note the enrollment measure is "gross enrollment" which can be greater than 100% since it is the ratio of total enrollment in a grade level divided by the population of the age group typically served by that grade, multiplied by 100). The countries eliminated fees in various years between 1994 and 2012. (**41 points**)

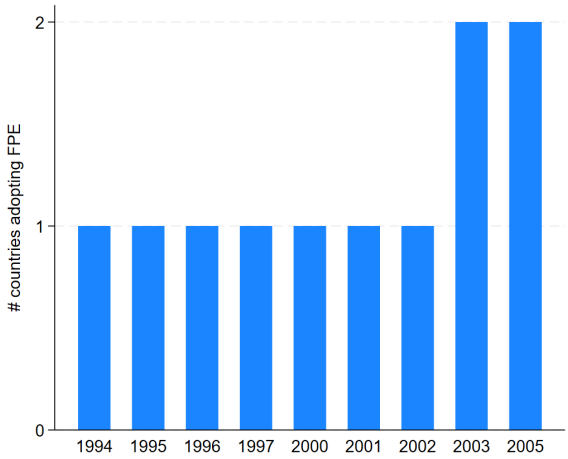
(a) In Stata, open the panel dataset called *WDI-FPE-data.dta* from Github:

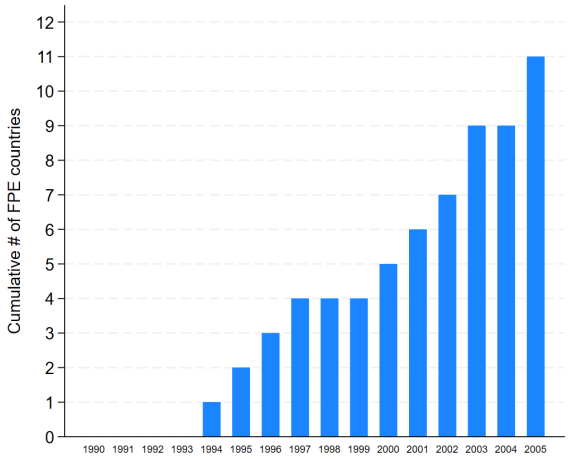
For this problem, drop all observations from 2006 and later. All countries were eventually treated in this panel, and we would like to have some "never treated" cases for sake of this problem. After doing this, create a table and an accompanying bar graph that shows the years treatment occurred for countries in this panel. (You may decide on the format for these). How many "timing groups" are there? How many "never treated" countries are there? (**5 points**)

See attached log and figure below. By 2005, 11 countries had eliminated their primary school enrollment fees. Based on the top figure there are 9 different treatment timing groups. Since there are 15 countries in the dataset, there are 4 never-treated countries.

(b) Use `xtset` to declare the data as a panel. Is this a balanced panel? (**2 points**)

See attached log. This is a balanced panel, with 15 countries observed for 25 periods each. However—as noted below—some countries have missing data on the outcome variables in select years.





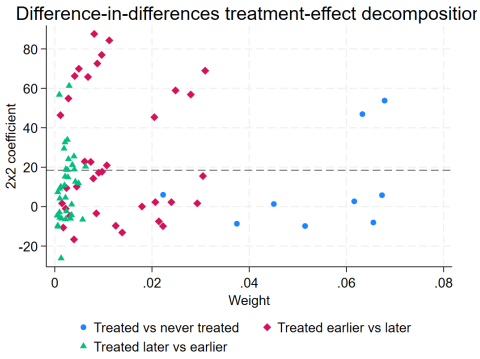
(c) Estimate the effect of eliminating fees on (i) primary school enrollment, and (ii) secondary school enrollment using "generalized difference-in-differences." For each, implement the two-way fixed effects regression model via `xtreg` and `xtdidregress`. When using `xtreg` be sure to cluster your standard errors appropriately. Briefly summarize your results. (**5 points**)

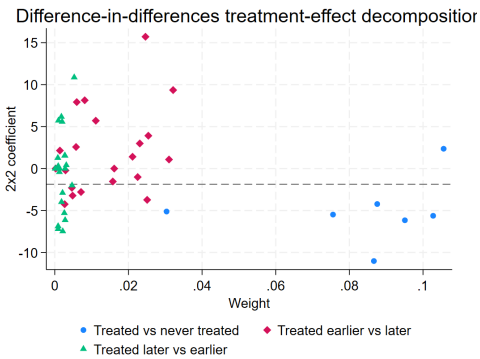
See attached log. Countries that eliminated primary school fees saw their gross enrollment rate increase 19.2 points, on average, relative to countries that did not. (Both `xtreg` and `xtdidreg` yield the same result). The estimate is statistically significant at the p=0.10 level. The point estimate for secondary enrollment is a statistically insignificant -1.46 points.

(d) (Quietly) re-run the `xtdidregress` command in part (c)—for both outcomes—and follow each by the post-estimation command `estat bdecomp` which provides the Bacon decomposition. Include the `graph` and `summaryonly` options. Explain in words what

the results tell us. (**5 points**)

See attached log and figures below. This command decomposes the TWFE estimate into all possible 2x2 difference-in-differences based on timing groups. The decomposition summary shows the combined ATEs for three groups: treated vs. never treated, treated earlier vs. later, treated later vs. earlier. It also shows the applicable weight for each group. The problematic group is the treated later vs. earlier. If the ATEs for this group are quite different and they receive a meaningfully large weight, the TWFE model may be misleading. Setting that aside, if the other two group averages are quite different from one another (and both receive significant weights), this may itself suggest a heterogeneous treatment effect model is appropriate. For the primary enrollment regression, the problematic group does not receive much weight (0.087), but the other two group estimates are quite different. For the secondary enrollment regression, all of the estimates are quite different, and are even of different sign. NOTE: it is not clear why the ATET reported in the `bdecomp` (18.4) differs from the one reported by `xtdidregress` (19.1). I think this may have to do with the small number of missing values on the outcome variable—the Stata manual says this command requires the panel be strongly balanced. When I replicated this with a dataset that was not missing values, the results were consistent with each other.





(e) The Stata command `xthdidregress` was created to implement a variety of estimators that allow for heterogeneous treatment effects and address the biases of traditional TWFE estimators when there is staggered treatment timing. Estimate the effect of eliminating fees on primary school enrollment using (i) the Wooldridge (2021) modified TWFE estimator, and (ii) the Callaway and Sant'Anna regression adjustment estimator. These are estimated using `xthdidregress twfe` and `ra`, respectively. (It may help to refer to the Stata help and documentation). Note the default is to use the never-treated as the comparison group. Explain in words how to interpret the regression output (in general, not each specific estimate). (**6 points**)

See attached log. Both approaches estimate separate treatment effects for each treatment timing group and post-treatment time period (Callaway-Sant'Anna also estimates treatment effects for the pre-treatment periods). The Wooldridge model does this using a modified TWFE with group and *post*-treatment period effects and interactions between each timing group and post-treatment period. The Callaway and Sant'Anna approach estimates separate treatment effects for each treatment timing group and year, using the never treated group as the comparison by default. The `ra` version of C-S regresses the change over time in Y on covariates X *in the never treated group* to get predicted changes for all units based on their X. It then calculates ATEs based on the actual change relative to predicted. (Note we have no covariates in this problem, so we are just calculating simple differences in mean changes in Y over time).

In the Wooldridge TWFE approach, treatment effect estimates are in reference to prevailing differences over the *full pre-treatment period*. For example, taking the 1997 cohort as an example, countries that eliminated fees in 1997 saw a comparatively larger increase in gross enrollment of 49.0 in 1997, relative to existing differences in the pre-treatment period. Likewise, they saw a comparatively larger increase in gross enrollment of 55.3 in 1998, relative to existing differences in the pre-treatment period, and so on.

In the C-S approach, the pre-treatment effects contrast *year-to-year changes* for the cohort and the never-treated group. Note these are not comparisons with the time period before treatment. For example, take the 1994 treatment cohort. The 1993 TE estimate contrasts the 1992-to-1993 change for this cohort to the 1992-to-1993 change for the never treated. Similarly, the 1992 TE estimate contrasts the 1991-to-1992 changes, and so on. This is why an estimate for the period before treatment is possible and not an omitted gorup. In the post-treatment periods, the contrast is always with the year before treatment, as you would see in an event study. Note the original C-S Stata package `csdid` actually makes this more transparent through better labeling.

(f) (Quietly) re-run the `xthdidregress ra` command in part (e) and follow it by the post-estimation commands below. Briefly explain what each does. Is there evidence of heterogeneous treatment effects by timing group? By event time? How do these results compare to the traditional TWFE estimates in part (c)? Based on the *dynamic* plot, in what post-treatment years is the treatment effect statistically significant? Finally, explain why the standard errors get larger in this plot over time. (**8 points**)

```
estat aggregation
estat atetplot
estat aggregation, dynamic graph
estat aggregation, cohort graph
```

See attached log. The aggregation commands combine the many point estimates from part (e) in meaningful ways. `estat aggregation` **by itself provides an overall ATE estimate for the post-treatment period. In our case, this is 18.4—not all that far off from the original TWFE estimate. The** `dynamic` **option provides an aggregate ATE estimate for each pre and post-treatment period—i.e., combining across treatment timing groups. The** `cohort` **option provides an aggregate post-treatment period effect for each treatment timing group. The figure below shows the time period and cohort specific aggregates. In the dynamic plot, estimates are statistically significant at the 0.05 level in leads 1, 2, 3, 4, 6, and 10, corresponding to year 2-5, 7, and 11 of treatment. The standard errors get larger over time in part because there are fewer observations with data this many periods after treatment.**

`atetplot` **provides a separate event study for each treatment timing group. This plot is also shown below.**

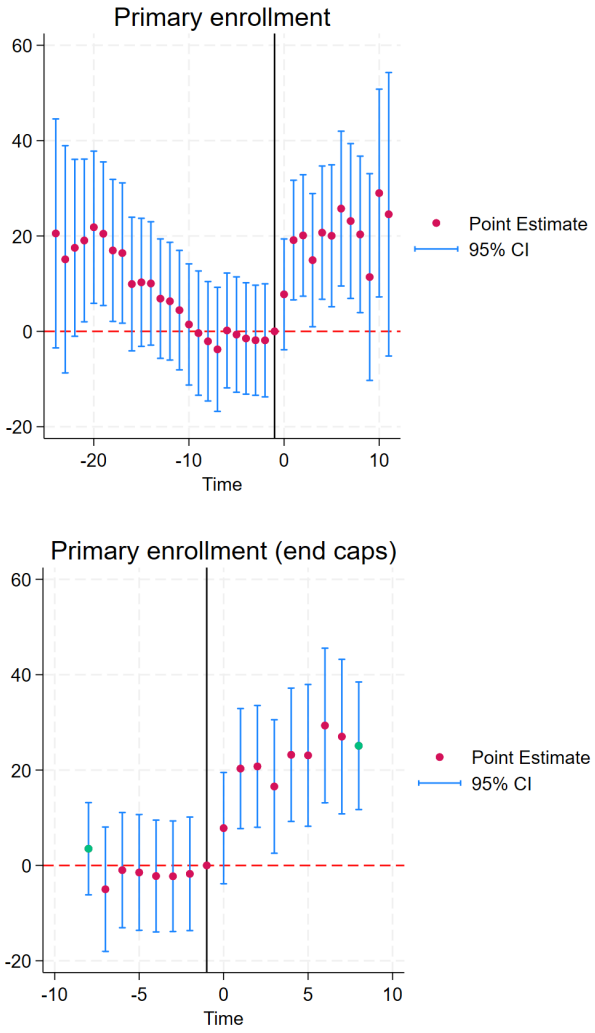
(g) As an alternative approach, use the command `eventdd` to estimate an event study model for primary school enrollment. Create your *event time* variable carefully, and use the option `method(fe)` to include country fixed effects. Be sure to also include calendar year effects. In words, interpret the *lead4* and *lag4* coefficients. Does the event study plot support the parallel trends assumption? Briefly explain. (**6 points**)

See attached log and figure below. The *lead4* coefficient of -1.49 tells us that gross enrollment in treated countries was -1.49 points lower than untreated countries in period *t-4* as compared to their prevailing difference in period *t-1* (one year before treatment). This difference is not statistically significant, however. The *lag4* coefficient of 20.7 tells us that gross enroll-

ment in treated countries was 20.7 points higher than untreated countries in period $t+4$ as compared to their prevailing difference one year before treatment. The pattern of pre-treatment differences suggest a convergence between the treated and untreated countries prior to treatment. However, few of these point estimates are statistically different from zero.



(h) Modify your `eventdd` syntax in part (g) to include the `accum` option and to consolidate "8 or more" time periods before and "8 or more" time periods after into one parameter (each). (See the `eventdd` help menu). (**4 points**)

See figure above. This is a good example of how the use of endcaps improves precision and results a cleaner event study diagram, while potentially concealing the trend visible in the top graph.

.
.         // Callaway and Sant'Anna (2021)
.         xthdidregress ra (primary) (treatment), group(country2)
note: variable _did_cohort, containing cohort indicators formed by treatment
      variable treatment and group variable country2, was added to the
      dataset.

Computing ATET for each cohort and time:
Cohort 1994 (24): ..........10.....x....20.x.. done
Cohort 1995 (24): ..........10..........20.... done
Cohort 1996 (24): ..........10......x...20.... done
Cohort 1997 (24): ..........10..........20.... done
Cohort 2000 (24): ..........10.x........20.... done
Cohort 2001 (24): ..........10..........20.... done
Cohort 2002 (24): ..........10xx...x....20.x.. done
Cohort 2003 (24): ..........10....xx....20.... done
Cohort 2005 (24): ..........10..........20.... done

Treatment and time information
